Neutral atoms have the same number of protons and electrons and, therefore, have no net charge. Metallic atoms generally give up electrons in chemical reactions to form ions which have more protons than electrons. These ions have a net positive charge. Ions bearing a positive charge are called cations. The metallic cations are named by giving the name of the metal followed by the word "ion". For example, Li⁺ is called "lithium ion". We can predict the net charge on the cation from the position of the atom in the Periodic Table. The elements in Groups 1 and 2 have a charge of +1 and +2, respectively. Many metals form more than one common cation, each with a different charge. With the exception of scandium and copper, the first row of the transition metals form a +2 ion and more highly charged ions as well. Copper forms +2 and +1 ions.

Nonmetal atoms generally accept electrons in chemical reactions to form ions which have more electrons than protons. These ions have a net negative charge. Ions bearing a negative charge are called anions. The monatomic anions are named by adding the suffix "ide" to the nonmetal root name and then the word "ion". Examples are F⁻ which is named the "fluoride ion" and N³⁻ which is the "nitride ion". The net charge of these ions can be obtained by counting the number of columns to reach Group 18. Nitrogen is in Group 15 which is three columns from Group 18, so the nitride ion has a -3 charge (written "3⁻").

The following Periodic Table shows the common ions of the elements that you probably would be expected to know.

EXAMPLE The symbol for the aluminum ion is Al³⁺. Aluminum is a metal and forms positively charged ions. We predict the charge will be +3 because Al is in Group 3. Nonmetals form negatively charged ions, called anions. The name of the Se²⁻ ion is selenide ion. Se is the symbol for selenium. Monatomic anions are named using the nonmetal root name with an "ide" suffix.
